

Computational Mathematics in Algebra Teaching Process

Paola A. Szekieta, Alicia M. Tinnirello, and Eduardo A. Gago

Abstract—In this work the authors present a mathematic laboratory experience where the concepts of discrete dynamic systems are introduced in Algebra and Analytical Geometry subject with the purpose of using computer packages to familiarize students with recent developments at an early stage, in this case cellular automaton models are used as a dynamical system with discrete values in space, time and state. In this experience, computer scientists and mathematicians work together to carry out interdisciplinary projects which present discrete data management to first-year engineering students. Starting from the theoretical concepts, different cellular automata have being presented with interesting applications for connecting and integrating the computational mathematics in engineering teaching process.

Keywords—Discrete dynamic systems, cellular automata, computational mathematics.

I. INTRODUCTION

SIMPLE problems can be formulated, increasing the difficulties using simple programming assignments algorithms and generating a gradually process where students arrive at complex works that would have involved time-consuming efforts without computer support.

This innovative activity is carried out by the Computer Laboratory of Basic Science of our University in order to introduce the mathematical developments to discrete variable events. The starting point is not whether content or processes have priority in the learning process, but making sure that learning becomes meaningful and functional.

Computer tools currently available are used to develop students' skills in the design of mathematical modeling with one discrete variable by teaching the fundamental basics of cellular automata (CA) in order to show the existing relations with symbolic calculus and the applications which these have with system resolution and modeling.

These applications are wide, ranging from microscopic simulations of Physics and Biology to macroscopic simulations of social and geological processes (Our translation) [1].

CAs are among the simplest mathematical representations of dynamical system that consist of more than a few – typically nonlinearly – interacting parts [2].

As such CAs are extremely useful idealizations of the dynamical behavior of many real systems, including physical fluids, molecular dynamical systems, natural ecologies,

military command and control networks, economy fire spreading, epidemiology and many others [3] [4]. Because of their underlying simplicity CAs are also powerful conceptual engines with which to study general pattern formation [2].

CAs consists of a regular array of identically programmed units called cells or sites that interact with their neighbors' subjects to a finite set of rules prescribed by local transitions. All sites make a regular lattice and they evolve in discrete time steps as each site assumes a new value based on the values of some local neighborhood of sites and a finite number of previous time steps [5].

As M. Resnick suggests, the performance of this model is governed, not by a centralized authority but by the local interaction among decentralized components [6].

Researchers have tried to develop different algorithm which can model different applications, in the beginning of the eighties Stephen Wolfram studied a family of simple one-dimensional CA rules, famous as Wolfram rules, and these simplest rules are capable to represent complex systems.

According to Wolfram: CAs are examples of mathematical systems constructed from many identical components, each simple, but together capable of complex behavior [7]. Some basic characteristics as regards the structure which the CA has are described. They represent a discrete system where the space, the time and the states of the system are all discrete and have the following properties: Space is represented by a regular lattice in one, two, or three dimensions; each site, or cell in the array of the CA can be in one of a finite number of states [8].

II. BACKGROUND ON CELLULAR AUTOMATA

From a theoretical point of view, some main concepts play an important role in CAs models:

A. *The physical environment*

This defines the universe on which the CA is computed. This underlying structure consists of a discrete lattice of cells with a rectangular, hexagonal, or other topology. Typically, these cells are all equal in size; the lattice itself can be finite or infinite in size, and its dimensionality can be 1 (a linear string of cells called an elementary cellular automaton), 2 (a grid), or even higher dimensional. In most cases, a common—but often neglected—assumption, is that the CAs lattice is embedded in a Euclidean space [3].

B. The cells' states

Each cell can be in a certain state, where typically an integer represents the number of distinct states a cell can be in, e.g., a binary state. Note that a cell's state is not restricted to such an integer domain; a continuous range of values is also possible, in which case we are dealing with coupled map lattices. We call the states of all cells collectively a CAs global configuration. This convention asserts that states are local and refer to cells, while a configuration is global and refers to the whole lattice [3].

C. Neighborhood

The neighborhood of a lattice site consists of the site itself and its nearest neighbor sites, called *neighbors*. The size of neighborhood is the same for each cell in the lattice. In the simplest case, i.e. a one-dimensional lattice, the neighborhood consists of the cell itself plus its adjacent cells. In a two-dimensional rectangular lattice there are two kinds of neighborhoods that are commonly defined:

A Von Neumann neighborhood consists of the site and the four nearest neighbors, situated above, below, right and left as shown in Fig.1 below.

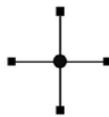

Fig. 1 Von Neumann neighborhood

A Moore neighborhood consists of the site and the eight nearest neighbors as shown in Fig.2 below.

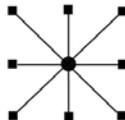

Fig. 2 Moore neighborhood

D. Lattice Boundaries. Periodic Boundaries

The nearest neighbors of sites along the sites of a lattice are determined differently for various boundary conditions. The way these conditions are defined will impact directly on the automata behavior. The periodic boundaries which are used in the modeling of the CA used in the target activity are defined. To illustrate this criterion, the corresponding Moore neighborhoods are shown below for each site in the following simple lattice:

1	2	3
4	5	6
7	8	9

This type of boundaries is defined when the neighbors of the sites on the borders of the lattice are set in the following way:

9	7	8	7	8	9	8	9	7
3	1	2	1	2	3	2	3	1
6	5	4	4	5	6	5	6	4
3	1	2	1	2	3	2	3	1
6	4	5	4	5	6	5	6	4
9	7	8	7	8	9	8	9	7
6	4	5	4	5	6	5	6	4
9	7	8	7	8	9	8	9	7
3	1	2	1	2	3	2	3	1

The nearest neighbor left of a site on the left border is the site in the same row on the right border. In the same way, the neighbors on the right of the cells on the right border are analyzed. The nearest neighbor above site on the top border is the site in the same column on the bottom border. In the same way, the neighbors on the bottom order are analyzed.

E. Evolution Rule

Another basic component worth mentioning is the Evolution Rule which defines the state of each cell according to the immediate previous state of the neighborhood. This evolution is determined by a mathematical function which captures the influence of the neighborhood over the target cell.

F. Virtual Clock

The virtual clock is a clock which will generate simultaneous ticks to every cell indicating that the evolution rule must be applied to modify or maintain the state of the cell. This component fulfills the parallelism condition, i.e. all the cell area updated at the same time [9].

III. GAME OF LIFE ALGORITHM

The Game of Life, which was created by the British mathematician J. H. Conway in 1970s, is the most famous CA. More computer time has been spent on running this game than on any other calculation and it was the first program executed by the *Connection Machine*, the world's first parallel computer. According to Gaylord & Wellin: it is the forerunner of so-called artificial life (or a-life) systems which are of great interest today, not only for their biological implications, but for the development of so-called intelligent agents for computers [5].

This automaton is a game of zero players, which implies that its evolution is determined by its initial set-up and there is no need of any further data entry. The game unfolds over a bidimensional grid as the game board. Each position on the board is called *cell* and it has 8 neighbor cells which are the nearest to each of them, including the diagonal ones (Moore neighborhood). The cells have two states, *living* or *dead*, which are represented by the numbers 1 and 0 respectively. The number and arrangement of living cells on the board

evolve along the discrete time units. All cell states are taken into account to calculate their state in the following time. All cells are updated simultaneously. The transitions depend on the number of neighbor cell which are alive. A dead cell with exactly 3 living neighbors will be born in the next turn. If a living cell has 2 or 3 neighbor living cells, the following turn it will still be living. In any other case, it will die or remain dead due to *loneliness* or *overpopulation*.

The game set out will continue until 2 identical consecutive states are obtained, or rather, until a certain number of predetermined transitions are reached.

To start the modeling of this game, an initial cell array over the board is set at the time $t = 0$, represented by the following grid:

$$\begin{matrix} 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{matrix}$$

Fig. 3 below shows each element on the board and its neighbors considering a Moore neighborhood with periodic boundaries.

$$\begin{pmatrix} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 1 \end{pmatrix} & \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 1 & 0 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \\ \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} \\ \begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 1 & 0 \end{pmatrix} & \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} \\ \begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 1 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} & \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} & \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \end{pmatrix}$$

Fig. 3 Moore neighborhood on initial grid

It is possible to determine the number of living neighbors in each of the initial positions, counting the numbers of living neighbors which are around each cell:

$$\begin{matrix} 4 & 3 & 2 & 2 \\ 4 & 3 & 3 & 3 \\ 4 & 4 & 2 & 3 \\ 3 & 3 & 2 & 3 \end{matrix}$$

Comparing the state of each cell of the game board in time t and the number of living neighbors, the following state in time $t + 1$ can be set up.

Fig. 4 below shows the transition from initial time $t = 0$ to $t = 1$. To visualize some examples, if we consider the state of the second element on first board row, it has 3 living neighbors

so this cell will be born at $t = 1$ but first cell on third row of the board will be dead at next turn due to overpopulation.

$$\begin{matrix} 0 & \textcircled{0} & 0 & 1 & & 4 & \textcircled{3} & 2 & 2 & & 0 & \textcircled{1} & 0 & 1 \\ 1 & 1 & 0 & 0 & \text{and} & 4 & 3 & 3 & 3 & \rightarrow & 0 & 1 & 1 & 1 \\ \textcircled{1} & 1 & 0 & 0 & & 4 & 4 & 2 & 3 & & \textcircled{0} & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & & 3 & 3 & 2 & 2 & & 1 & 1 & 0 & 1 \end{matrix}$$

$t = 0$ $t = 1$

Fig. 4 Evolution from $t = 0$ to $t = 1$

Fig. 5 shows evolution from $t = 1$ to $t = 2$. On the last row of the game board two cases of surviving rules are highlighted.

$$\begin{matrix} 0 & 1 & 0 & 1 & & 7 & 4 & 7 & 4 & & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & \text{and} & 5 & 2 & 5 & 3 & \rightarrow & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & & 6 & 4 & 6 & 4 & & 0 & 0 & 0 & 0 \\ 1 & \textcircled{1} & 0 & \textcircled{1} & & 5 & \textcircled{2} & 5 & \textcircled{3} & & 0 & \textcircled{1} & 0 & \textcircled{1} \end{matrix}$$

$t = 1$ $t = 2$

Fig. 5 Evolution from $t = 1$ to $t = 2$

At the time instance $t = 3$, a board with all dead cells is obtained as shown in Fig. 6 below. The following turn, time $t = 4$, the same result will be obtained, so the game will finish by obtaining two consecutive similar states.

$$\begin{matrix} 0 & 0 & 0 & 0 & & 4 & 3 & 5 & 3 & & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & \text{and} & 2 & 1 & 2 & 1 & \rightarrow & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & & 4 & 3 & 5 & 3 & & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & & 2 & 0 & 2 & 0 & & 0 & 0 & 0 & 0 \end{matrix}$$

$t = 3$ $t = 4$

Fig. 6 Evolution from $t = 3$ to $t = 4$

IV. LABORATORY PROJECT: DEFINING AND DEVELOPING A COMPUTATIONAL SIMULATION MODEL

In the context of meaningful learning, the students' activities must be oriented in a school system based on research and development of appropriate strategies for connecting and integrating the computational mathematics and the basic technologies and applied in Engineering to promote the multidisciplinary approach to the curriculum content corresponding to the plans of study, aiming to train professionals capable of solving complex models with the use of technologies.

The existence of simulation tools transformed the programming environments toward more collaborative spaces, with the updated listings of increasingly complex systems but with broad application in the various areas that comprise the engineering, it is possible to design methodological strategies

that integrate the knowledge of the compartmentalized disciplines.

The developments that have experienced the mathematical software and the affinity that the students have to be linked with the technologies, imposes on the university teachers makes the effort to transform the teaching-learning process in the process of learning investigating [10].

The present experience shows the representation of the Game of Life using specific software (MATHEMATICA, Wolfram Research). To do this, the board and the way neighborhood for each cell is obtained as well as the transition rules should be set up.

The board is represented by a square matrix of order 4 St, and each of its entries is the state of a particular cell at a given time t .

The following step is to define the function which returns the number of neighbors alive of each cell of the board. To model this automaton, the Moore neighborhood is considered which is made up by the 8 neighbors around the position which is often identified with a cardinal point according to the position of the central cell: north, northeast, east, southeast, south, southwest, west and northwest. Fig. 7 below shows this Moore neighborhood.

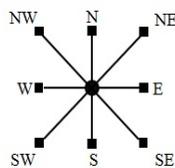

Fig.7 Moore neighborhood

It is possible to obtain a matrix that shows a particular neighbor by performing elementary operations on S_t .

For example, to obtain a matrix N_t whose elements n_{ij} represent north neighbor of each site s_{ij} in S_t at a certain time t , it is necessary to move down every row on S_t by properly interchanging them. Ec. (1) shows N_o that is north neighbors of each site s_{ij} at time $t = 0$.

$$\begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \xrightarrow{\substack{f1=f4 \\ f2=f1 \\ f3=f2 \\ f4=f3}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix} = N_o \quad (1)$$

To find the matrix NE_o whose elements represent the neighbor in the Northeast position of each s_{ij} in S_o , first move the rows (f) downwards as shown in (1) above and then, on this resulting matrix, interchange columns (c) to the left. See (2) below.

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix} \xrightarrow{\substack{c1=c2 \\ c2=c3 \\ c3=c4 \\ c4=c1}} \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \end{pmatrix} = NE_o \quad (2)$$

Similarly, it is possible to obtain matrices that show a particular neighbor for each position in the state space and therefore to know the number of living neighbors of s_{ij} adding these 8 matrices of neighbor positions.

$$\begin{aligned} & \underbrace{\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix}}_{N_o} + \underbrace{\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \end{pmatrix}}_{NE_o} + \underbrace{\begin{pmatrix} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}}_{E_o} + \underbrace{\begin{pmatrix} 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}}_{SE_o} + \\ & + \underbrace{\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}}_{S_o} + \underbrace{\begin{pmatrix} 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}}_{SW_o} + \underbrace{\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}}_{W_o} + \underbrace{\begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \end{pmatrix}}_{NW_o} = \\ & = \begin{pmatrix} 4 & 3 & 2 & 2 \\ 4 & 3 & 3 & 3 \\ 4 & 4 & 2 & 3 \\ 3 & 3 & 2 & 3 \end{pmatrix} = V_o \end{aligned}$$

Fig. 8 Number of living neighbors' matrix at $t = 0$

Fig. 8 above shows how to obtain number of living neighbors matrix at time $t = 0$.

Analyzing values of homologous elements on S_t and V_t , the next state into which s_{ij} will evolve can be obtained.

The evolution rule is function to the state of a cell s_{ij} and the number of living neighbor which it has.

Rule [st_{ij} : cell state s_{ij} , vt_{ij} : number of living neighbors s_{ij}] = $st + l_{ij}$.

A living site with two living nearest neighbor sites remains alive: $Rule[1,2]=1$.

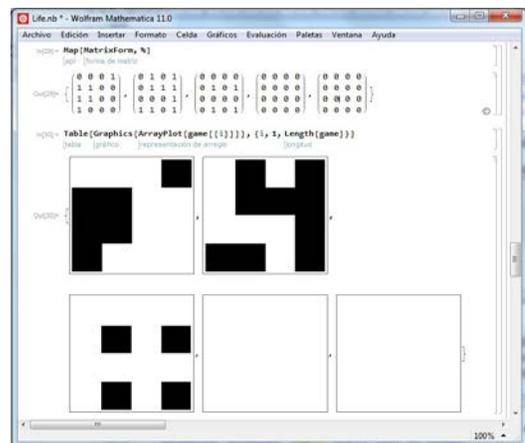

Fig. 9 Game consecutive states

Any site (no matter if living or dead) with three living nearest neighbor sites stays alive or is born: $Rule[_,3]=1$.

All other cases, one cell either remains dead or die: $Rule[_,_]=0$.

The following matrices: $S_0; S_1; S_2; S_3$ and S_4 show the consecutive states which the game reaches at each instance t . Matrices can be represented graphically with a black site for living cells and a white one for dead cells. Fig. 9 shows both representations.

The number of different 2D geometric cellular automata that can be constructed from all possible rules is unimaginably large. For simple binary cells, with 8 neighboring cells there are 8+1 cells that influence a given cell (previous state of a cell can influence it's next state), which leads to 2^{512} possible binary combinations or approximately 10^{154} different CAs, of which the Game of Life is only one of them. In general, for an Nth Dimensional Geometric CA with (m) neighbors, there are $2k$ possible rules available for the Cellular Automata, where $k = 2^{m+1}$ [11].

Game of Life rules are simple enough for anyone to understand, yet they lead to an endless number of different patterns, and to significant complexity [11]. Such as gliders, guns, puffers, 'oscillating' particles with different translation rates and spontaneous particle emission from some oscillating patterns among others.

It is interesting to observe different these patterns or *life forms*. In the evolution space there are four classes of behavior:

- 1) Evolution leads to a homogeneous state, in which all cells eventually attain the same value
- 2) Evolution leads to either to simple stable states or periodic or separated structures
- 3) Evolution leads to chaotic nonperiodic patterns
- 4) Evolution leads to complex, localized propagating structures.

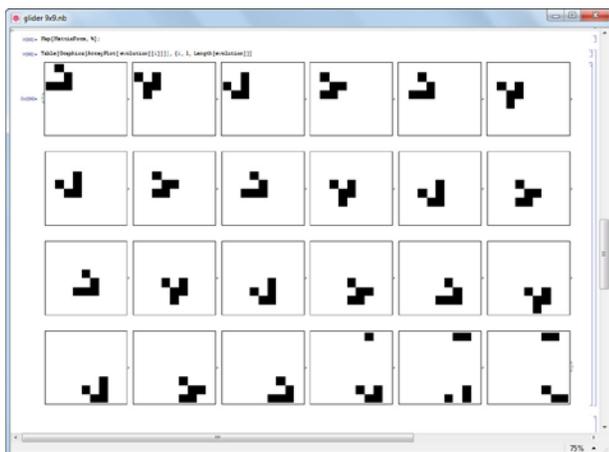

Fig. 10 Glider pattern

One of the most intriguing pattern is an oscillatory propagating pattern known as *glider*, shown in Fig. 10, it

consist of five living cells and reproduces itself in a diagonally displaced position once every four iteration.

Software allows visualizing an animation of any pattern evolution, shown in Fig 11. Glider gives the appearance of *walking* across the screen.

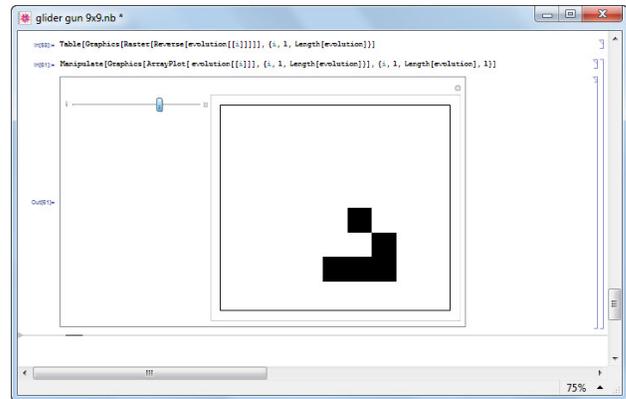

Fig. 11 Glider pattern animation

There are some distinct moving self-replicating figures, which are individually referred to as *spaceships*. Unlike the glider, these spaceship figures are horizontally displaced. See Fig. 12

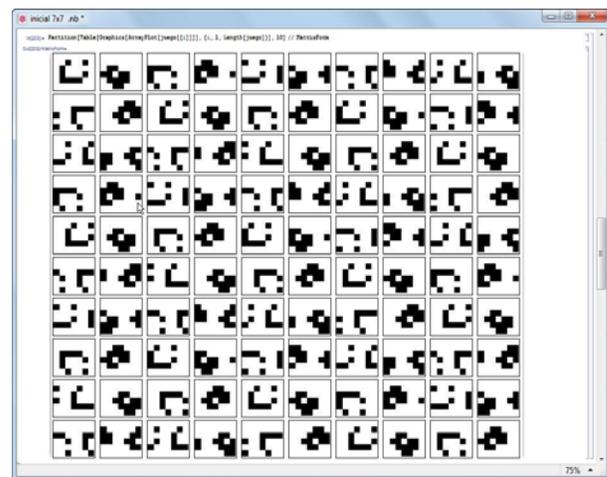

Fig. 12 Spaceship pattern

Fig.13 shows a pattern that disappears within a number of iteration:

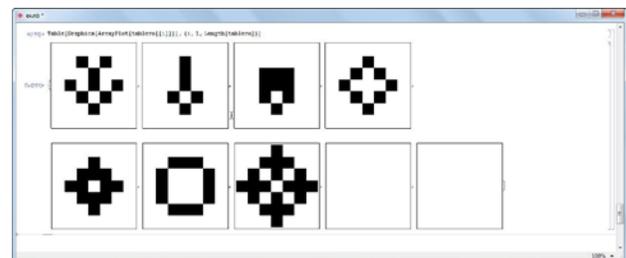

Fig. 13 Cross pattern

Some initial configurations reach a stable state which does not change or disappear, as seen in Fig. 14

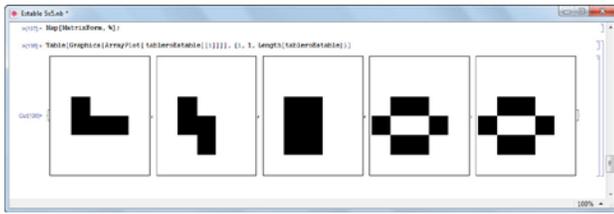

Fig. 14 Stable pattern

Live cells survive only if surrounded by two or three cells and a new cell is born only if surrounded by exactly three living cells. Initial configurations consisting of either single or neighboring live cells immediately yield the null state.

Survival in Game of Life requires a minimum of three living cells. Fig.15 shows the fate of one three-live initial state; its evolution is a period-2 state. Structures that lead into a periodic behavior are called oscillators.

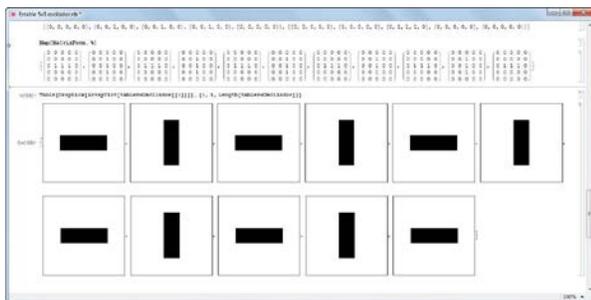

Fig. 15 Oscillator

In general, it's not possible to predict whether a particular starting configuration will eventually die out or not. There is no short-cut rout to the final outcome of this game's evolution, it is necessary to await game's own final outcome.

Combining several gliders in one single lattice produces different behaviors. Fig.16 below shows evolution resulting of combining two gliders placed in two opposite corners of a rectangular lattice. Game reaches null configuration in seventeen time-steps.

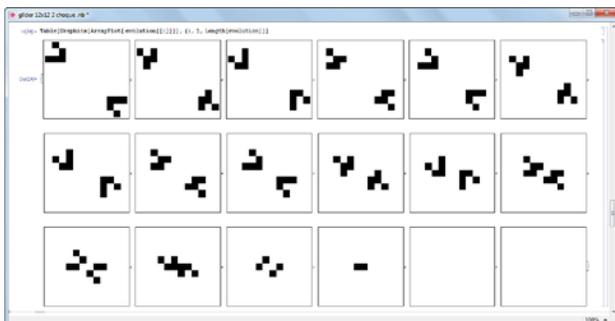

Fig.16: Evolution of two gliders

Fig. 17 below shows game's evolution from a starting configuration that combine three gliders placed in different corners of a rectangular lattice. The final state of this pattern is a stable oscillatory pattern.

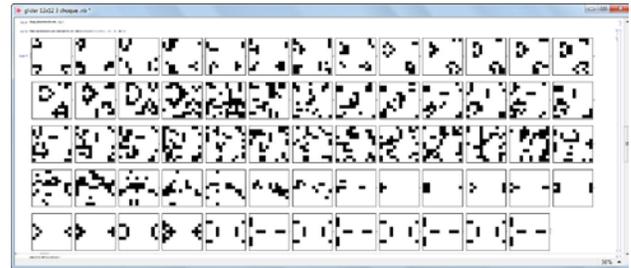

Fig. 17 Evolution of three gliders

Placing four oscillator patterns on the same board evolves into a stable pattern after nine iterations as shown in Fig. 18 below.

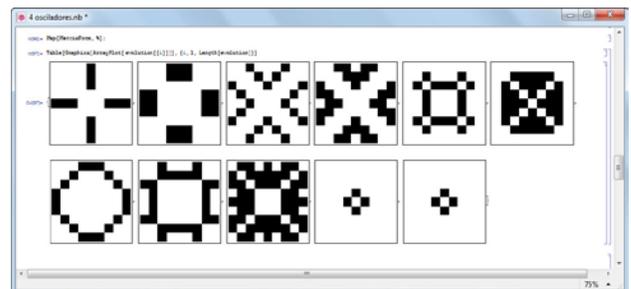

Fig. 18 Evolution of four oscillator pattern

From Fig. 19, we observe a pattern, called R-pentamino, which evolution is wildly unstable, expanding outward and continually undergoing change while scattering various bits of debris in all directions. This continues for many iterations steps marking a time beyond which all the various local patterns remain isolated and noninteracting. The significance of this evolution actually lies in the appearing of the oscillatory and propagating pattern known as glider [11].

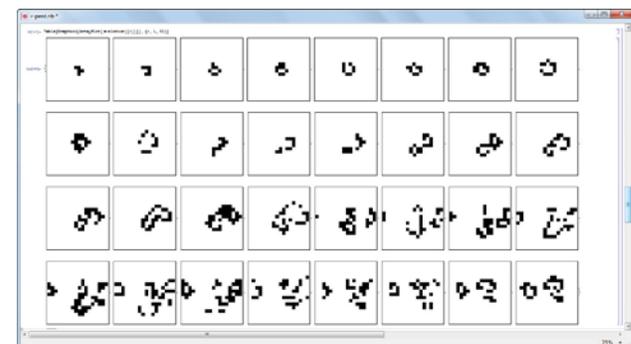

Fig. 19 R-pentamino initial evolution

Students investigated these patterns and modified initial set-up to watch diverse evolution processes of the game.
